ABSTRACT

Self-referential processing is critical to understanding social anxiety disorder (SAD). This study examined neural differences in self-referential processing in healthy controls (HC) and participants with SAD at pre- and post-treatment. Participants (n = 64) underwent fMRI scanning while viewing a video of themselves (“Self”) or another person (“Other”). SAD participants were randomized to cognitive behavior therapy (CBT), acceptance and commitment therapy (ACT), or waitlist, and were re-scanned at post-treatment. In SAD vs. HC, the fusiform face area (FFA) showed significantly more activation during Self vs. Other, and greater SAD severity was associated with significantly more activation during Self vs. Other in the right FFA and the left extrastriate body area (EBA). Greater reduction in SAD severity was associated with stronger connectivity between the amygdala and FFA during Self vs. Other at post-treatment, whereas the strength of connectivity during Self and Other was comparable at post-treatment for those with less SAD reduction. Thus, there were significant differences in activation and functional connectivity of brain regions implicated in self-referential processing in SAD. Change in connectivity between the amygdala and FFA were observed as a function of change in SAD severity, suggesting that improvements in SAD severity may correct this altered functional connectivity.

1. Introduction

Social anxiety disorder (SAD) is characterized by excessive concern with negative evaluation (American Psychiatric Association, 2013). While much is known about the clinical presentation of SAD and its treatment, less is known about neural mechanisms underlying core processes of SAD. The threat-detection neural circuitry underlying fears of negative evaluation involves the amygdala, precuneus, insula, anterior cingulate, and prefrontal cortices (Brühl et al., 2014; Etkin and Wager, 2007). However, beyond fears of negative evaluation, SAD is also characterized by altered self-referential processing, and this is likely reflected in unique areas of neural activation.

Rapee and Heimberg (1997) proposed that SAD involves negatively-biased mental self-representations. Self-representation is based on memories of social successes and failures. This self-representation is compared with an expected performance to predict the probability of an aversive outcome, such that the representation itself becomes aversive. Video-feedback may combat distorted mental representations by providing corrective learning experiences (Harvey et al., 2000). While several investigations have explored self-referential processing in response to language cues (i.e., criticism and praise; Blair et al., 2008; Abraham et al., 2013; Yoon et al., 2016) or in subclinical samples (Abraham et al., 2013), the neural mechanisms of self-referential processing in regard to videos of the self in SAD are not well understood. Given the importance of self-referential video feedback for treatment, it
is important to further understand the neural mechanisms underlying this task.

1.1. Neural Underpinnings of Self-Referential Processing in Healthy Controls

Meta-analytic findings suggest that three key steps are required for self-referential processing for videos of the self (Platek et al., 2008): (1) sensory processing in the fusiform, particularly in terms of stimulus detection for faces, which (2) relays information to the precuneus for processing of facial information, and then (3) to cortical areas, especially the middle frontal gyrus which is involved in the discrimination between self- and other-content. The fusiform gyrus, an area involved in face processing more broadly (which is related to the sensory processing of the first step in the model described above, Kanwisher et al., 1997), has previously been shown to be more active in response to images of the self- versus other-face (Sugiyama et al., 2005). In addition, the extrastriate body area (EBA), a brain region involved in processing of body stimuli, is likely involved in processing self- vs. other-referential body stimuli (Vocks et al., 2010). Cortical areas implicated in self-referential processing more broadly, particularly in stimuli other than videos of the self, have been shown to involve activation of the cortical midline structures (CMS), including the medial orbitofrontal cortex, ventromedial prefrontal cortex (vmPFC), dorsomedial PFC, dorsal anterior cingulate cortex, and precuneus (Northoff et al., 2006).

1.2. Neural Underpinnings of Self-Referential Processing in SAD

The fusiform face area (FFA), a key region in self-referential processing, is differentially activated in SAD compared to HC. When viewing images of fearful faces, SAD participants demonstrated greater reactivity in bilateral fusiform compared to HC (Frick et al., 2013). This suggests that the individuals with SAD might demonstrate altered sensory processing, specifically facial processing, compared to HC. When individuals with SAD and HC observed a video recording of their own working memory task performance, compared to others’ performance, differential activation in the fusiform was observed for those with higher SAD severity (Pujol et al., 2013). To our knowledge, this is the only study comparing self- to other-referential processing of videos in SAD and HC, and this study did not include observation of a speech performance task, a common therapeutic tool in SAD treatment.

Altered processing of bodily stimuli may also be critical in understanding disrupted self-referential processing in SAD. Individuals with greater levels of social inhibition, or the tendency to inhibit emotional expression in social relationships which often occurs in SAD, demonstrated greater activation of the EBA during observation of threatening versus neutral body movements (Kret et al., 2011). However, the importance of altered EBA activation in self-referential processing has not been extended to SAD. Differential activation in the EBA has been demonstrated during self-referential body processing in anorexia, bulimia, and unspecified eating disorders. Specifically, individuals with eating disorders who received treatment demonstrated increased activation in the EBA during self- versus other-body processing relative to individuals who did not receive treatment (Vocks et al., 2011). Thus, treatment for eating disorders may be associated with altered sensory processing, reflected in more activation of brain regions typically associated with processing of bodily stimuli. However, it is unclear whether self-referential bodily processing is altered in SAD or whether these alterations are corrected in response to treatment.

1.3. Neural Mechanisms of SAD Treatment

A few prior studies have described neural changes from pre- to post-SAD treatment. Young and colleagues (2017) found that in a sam-ple of patients with SAD who were assigned to cognitive behavior therapy (CBT) or acceptance and commitment therapy (ACT; Hayes et al., 1999), the degree of SAD reduction in treatment correlated with functional connectivity between the amygdala and ventromedial prefrontal cortex at post-treatment. Three additional studies have explored other implicit (Burkland et al., 2015) or explicit emotion regulation strategies in response to treatment for SAD, including internet delivered (Månnson et al., 2013), and in-person CBT (Goldin et al., 2013, 2014). However, none of the studies that have explored neural mechanisms of SAD treatment have reported on changes in neural activation during self-referential processing of a video observation task.

1.4. Current Study

In the current study, fMRI BOLD signal was recorded as participants with and without SAD observed video-recordings of their own (“self-observation”) and another person’s (“other-observation”) speech performance. We hypothesized that exposure to self-observation (vs. other-observation) would be associated with enhanced activation in regions associated with self-referential processing, namely the FFA, EBA and medial PFC, and regions associated with anxiety, namely the amygdala, in SAD compared to HC. We also hypothesized that severity of social anxiety across the entire sample would be associated with differential patterns of activation in the FFA and EBA, with greater social anxiety severity associated with greater activation during self- vs. other-observation. We explored functional connectivity between the right amygdala, given its role in fear conditioning (Marek and Sah, 2018), and all other brain regions during self- vs. other-observation for SAD vs. HC. We did not have a priori hypotheses about functional connectivity given the lack of prior research on this topic in self-referential processing for SAD vs. HC. Therefore, this was an exploratory aim. In addition, we examined changes in self-referential processing from pre- to post-treatment. We hypothesized that individuals who received an evidence-based treatment for SAD (namely CBT and ACT) would show a correction in disrupted neural activation during self-referential processing compared to individuals on a waitlist. As the parent trial from which these data were collected did not reveal any major treatment outcome differences between CBT and ACT (Craske et al., 2014), we did not anticipate any differences between the two active treatment comparisons in terms of neural activation. Finally, we compared functional connectivity at post-treatment, as well as the correlation between functional connectivity at post-treatment and SAD severity reduction from pre- to post-treatment. As with the baseline functional connectivity aim, these were exploratory aims.

2. Methods

2.1. Participants

Demographic and full methodological details are reported in Table 1 and in Craske et al. (2014). Participants were medication-free or stabilized (n = 8) on psychotropic medications and could not meet criteria for severe major depression, a history of bipolar disorder, psychosis, active suicide ideation, current substance abuse or dependence, or major medical problems. Individuals could not participate if they were pregnant, left-handed, had metal implants or claustrophobia.

2.1.1. Social Anxiety Participants

Individuals who met criteria for SAD, generalized type according to the Anxiety Disorders Interview Schedule (ADIS; Di Nardo et al., 1994), as indicated by a clinician severity rating greater than 4, were invited to participate (n = 100). The current study included 51 participants who completed the self-referential processing task.
2.1.2. Healthy control participants

HC (n = 13) were similar to all SAD participants on age and gender and did not meet criteria for any Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) mood or anxiety disorders.

2.2. Measures

2.3.1. Liebowitz Social Anxiety Scale-Self Report Version (LSAS; Liebowitz, 1987)

The LSAS is a 27-item measure of social anxiety severity that assesses both fear and avoidance of social and performance situations on a 0–3 point Likert scale. The LSAS has high internal consistency, as well as good convergent and discriminant validity (Fresco et al., 2001). As social anxiety disorder status was determined by a clinical interview and not self-report, the LSAS measure has sufficient variability, even within the HC condition (range 0–27 within HC) and can be used as a dimensional measure of social anxiety severity.

2.3. Procedure

The study took place at the Anxiety and Depression Research Center at the University of California, Los Angeles campus and was approved by the UCLA Human Subjects Protection Committee. Following completion of informed consent and the baseline assessment, participants attended a laboratory session in which they completed a variety of emotional reactivity and regulation tasks regarding public speaking. Participants were asked to give a three-minute video-recorded speech on two topics (global warming and corporal punishment). Two researchers observed the speech delivery. The researchers told participants that the recorded tape would be prepared so that other “impartial observers” could watch and evaluate their content and delivery. Researchers instructed participants to discuss one or both of the topics during the speech, and to prepare for 5 min prior to the speech. After preparation, participants were given a 2 min break to enhance speech anticipation.

Participants returned to the laboratory for a separate visit to complete the fMRI scan. The task for the current study included viewing two blocked presentations of separate 30 s videos of the participant’s speech (“Self”) interspersed with two presentations of 30 s news videos (“Other”) with a 10 s interstimulus interval. Researchers instructed participants as follows: “During the next scan, you’ll simply be watching video clips of yourself and others speaking. You will not need to make any button presses for this scan.”

“Other” stimuli consisted of two 30 s videos depicting standardized news reports of a well-known female news anchor, which was included to control for familiarity, movement and speech of the self-referential video observation task. The content of the videos included segments on invisibility technology and school yearbooks. “Self” stimuli included two idiographic 30 s videos depicting each participant delivering a previously recorded speech in the laboratory on a prior session, recorded from the waist up.

2.4. Therapy

Participants randomized to receive either CBT (n = 17) or ACT (n = 20) received 12 weekly, 1 h therapy sessions, whereas participants on the waitlist (n = 14) were invited to complete either treatment at the end of their final assessment. Full details on the therapy are available elsewhere (Craske et al., 2014). However, most participants completed therapy between 12 – 16 weeks from baseline (range 11 – 18 weeks). In the sample of participants who completed the task for the current study, mean LSAS severity scores from pre- to post-treatment were as follows: CBT Pre-treatment: 81.55 (SD = 15.75), Post-treatment: 61.82; (SD = 20.47); ACT Pre-treatment: 90.92 (SD = 21.25), Post-treatment: 66.75 (SD = 19.98), Waitlist Pre-treatment: 69.70 (SD = 22.43), Post-treatment: 69.70 (SD = 15.35). In each active condition, 4 participants dropped out of therapy.

2.5. Image acquisition and analysis

Data were collected on a Trio 3.0 Tesla MRI scanner at the UCLA Ahmanson-Lovelace Brain Mapping Center. High-resolution structural T2-weighted echo-planar images were acquired for each participant (spin-echo; TR = 5000 ms; TE = 34 ms, matrix size = 128 × 128, resolution 1.6 mm × 1.66 mm × 3 mm; FOV = 200 mm; 36 axial slices, 3 mm thick, flip angle = 90°, bandwidth = 1302 Hz/Px). Functional imaging used T2*-weighted echo planar image sequences (gradient-echo, TR = 3000 ms, TE = 25 ms, flip angle = 90°, matrix
size = 64 × 64, resolution 3.1 mm × 3.1 mm × 3.0 mm, FOV = 200 mm, 36 axial slices, bandwidth = 2604 Hz/Px, duration: 2 min 51 s, 1 functional run/participant, third task per run).

Data were analyzed using SPM8 (Wellcome Department of Cognitive Neurology, Institute for Neurology, London, UK). Functional images were realigned to the mean to correct for head motion, co-registered with high resolution structural images and warped into MNI space using the segmentation procedure in SPM8 (resampled at 3 × 3 × 3 mm; Mazzotta et al., 2001). Images were then smoothed using an 8 mm Gaussian kernel, full-width half-max and high pass filtered at 128 sec to account for low-frequency drift.

Statistical analysis of functional data used general linear models using a block design to model box car functions for the duration of video clips (30s), convolved with the canonical double-gamma hemodynamic response function (HRF) and including six motion parameters as covariates of no interest. Additionally, regressors identifying individual volumes with large global signal intensity change (outliers thresholded at 2.5 standard deviations from average global signal intensity within the run) or volumes with motion spikes (1.5 mm or greater) were included to remove variance in signal due to noise. Runs with more than 10% of volumes with large global signal intensity changes or motion spikes were removed from analyses. Contrast images were computed for the mean activation of ‘Self > Other’ and ‘Other > Self’.

For hypothesis 1, contrasts of interest in the whole-brain analyses included Self < or > Other, first for each group separately and then in a between-group, two-sample, one-sided t-test. Of note, SPM corrects for differences in sample size and heteroscedasticity by assuming unequal variance between samples and using restricted maximum likelihood (REML) and weighted least squares to produce maximum likelihood estimators using non-sphericity.

For hypothesis 2, a secondary whole-brain analysis included LSAS as a regressor for the same contrast. Specifically, we entered LSAS as a regressor of activation in SAD only, HC only, and in the two-sample SAD vs. HC comparison.

To address hypothesis 3, differential functional connectivity between SAD and HC with the amygdala as a seed region, given its role in threat-responsing for social anxiety disorder (Pape and Pare, 2010), we conducted psychophysiological interaction (PPI). A whole brain PPI analyzes anatomically defined regions of interest (ROI, using the AAL) of the right and left amygdala in each group separately and in a two-sample between group comparison.

To address hypothesis 4, differential activation from pre- to post-treatment for Treatment versus Waitlist and for CBT vs. ACT, we ran a two-sample t-test on the change in activation from pre- to post-treatment.

Finally, to address hypothesis 5, differential functional connectivity from pre- to post-treatment with the right amygdala as the seed region was calculated using PPI analyses in a two-sample between group comparison. To address hypothesis 6, this PPI analysis was repeated with change in LSAS entered as a covariate.

For all analyses, we determined cluster-size thresholds using Monte Carlo simulations in AFNI’s 3DClustSim (http://afni.nimh.nih.gov/afni/) which allowed for improved assessment of functional activation and correction for multiple comparisons (Forman et al., 1995) based on a grey matter mask. Given a priori interest in the FFA, an anatomical mask of the left and right FFA were also entered into 3DClustSim. These analyses resulted in a recommended resampled cluster size of 30.5 voxels for the left FFA; 32.9 voxels for the right FFA, and 39.3 voxels for the rest of the brain at an alpha level of 0.05 and a voxelwise threshold of p < 0.005 (two-tailed tests).

3. Results

3.1. Baseline

3.1.1. Hypothesis 1: Whole-brain group differences at pre-treatment
In a two-sample t-test, SAD had a greater difference in activation for the Self > Other contrast compared to HC in right middle occipital gyrus, extending into the right fusiform gyrus (see Table 2). For differences for Self > Other with HC and SAD separately, see supplemental material.

3.1.2. Hypothesis 2. Relationship of social anxiety severity to brain activation during Self-vs. Other-observation at pre-treatment
When LSAS was included as a regressor in the model, one region of activation included the right fusiform gyrus which was significant in the Self > Other contrast (see Table 2) and was extracted as an ROI to allow for graphing. LSAS was a significant predictor of the difference in activation for Self > Other in the right fusiform gyrus, and greater LSAS severity was associated with a greater activity in response to Self relative to Other (see Fig. 1). Other areas with significant activation in this Self > Other comparison in the same direction included the bilateral middle occipital gyrus. Activation in the left middle occipital gyrus included an area in the visual cortex that extended into the EBA.

3.1.3. Hypothesis 3. Differential functional connectivity with right amygdala seed in SAD vs. HC

3.1.3.1. Within-group functional connectivity
In HC, no suprathreshold clusters were detected in right amygdala-seeded functional connectivity analyses for the Self vs. Other contrast. In SAD, greater functional connectivity was detected to Other compared to Self in bilateral

fusiform, left middle frontal gyrus, and right frontal medial orbitofrontal gyrus, among other regions.

3.1.3.2. Between-group functional connectivity A right amygdala seeded PPI analysis found that, compared to HC, SAD participants showed greater functional connectivity for Self > Other in the right insula (see Table 2 and Fig. 2(a) and (b)). There was greater functional connectivity for Self > Other between the insula and amygdala in SAD compared to HC.

3.2. Pre- to post-treatment

3.2.1. Hypothesis 4. Differences from pre- to post-treatment

3.2.1.1. Treatment vs. waitlist A two-sample t-test comparing Treatment versus Waitlist from pre- to post-treatment on differences in Self > Other resulted in 6 significant clusters of activation, including in the left insula, anterior cingulate cortex, and parietal/occipital regions. Across all regions, the Treatment group demonstrated greater differential activation to Self > Other Contrast at pre-treatment compared to post-treatment (this pattern was reversed for Waitlist; see Table 3 and Fig. 3, as an example region in the left insula). Visual inspection of the direction of these effects demonstrated that activation to Self and Other decreased from pre- to post-treatment in the Treatment group, whereas activation to Self and Other increased from pre- to post-treatment in the Waitlist group.

3.2.1.2. CBT vs. ACT A two-sample t-test comparing CBT vs. ACT revealed only one significant region of differential activation in the putamen for Self > Other. This difference was driven by stronger activation in the putamen Self > Other in ACT relative to CBT.

3.2.2. Hypothesis 5: Functional connectivity

Across all groups at post-treatment, there was less of a difference in functional connectivity between the right amygdala and vmPFC for Self > Other relative to the difference at pre-treatment, where connectivity was stronger during Other compared to Self (see Fig. 4). When only the treatment group was analyzed, this effect was only marginally significant, possibly due to power.

3.2.3. Hypothesis 6: Functional connectivity by LSAS reduction

LSAS reduction was negatively correlated with change in functional connectivity between the right amygdala and right FFA. Specifically, those with greater reduction in LSAS demonstrated stronger connectivity during Self and weaker connectivity during Other at post-treatment, whereas the strength of connectivity during Self and Other was comparable at post-treatment for those with less LSAS change.

4. Discussion

Compared to healthy controls, individuals with social anxiety disorder demonstrated greater pre-treatment activation in the fusiform face area, a region implicated in self-referential processing (Kanwisher et al., 1997), during self-observation compared to other-observation. This finding is consistent with our first hypothesis, and with prior research in which emotionally evocative stimuli were associated with enhanced activation in the fusiform face area in individuals with social anxiety disorder (Frick et al., 2013). The current study extends...

Fig. 3. Pre- to post-treatment left insula activation during self- versus other-referential processing in the treatment and waitlist groups.

Fig. 4. Right amygdala to ventromedial prefrontal cortex (VMPFC) connectivity.

This work by demonstrating altered fusiform face activation during self-versus other-referential processing.

Furthermore, greater severity of social anxiety at baseline was associated with greater activation the fusiform face area during self-referential processing compared to other-referential processing. This finding is consistent with prior research in which differential activation of the fusiform face area was observed during self-observation of a working memory task based on severity of social anxiety symptoms (Pujol et al., 2013). Similar findings were observed when social anxiety severity was regressed on activation in the extrastrate body area, a region implicated in self-referential processing of body stimuli in clinical samples (Kret et al., 2011). Therefore, the second hypothesis was also confirmed.

Altered functional connectivity between the amygdala and the fusiform face area at pre-treatment was also observed in individuals with social anxiety disorder. In other words, the correlation in activation between the amygdala and the fusiform face area was more positive in individuals with social anxiety disorder during other-referential processing as compared to self-referential processing. At post-treatment, those who experienced a greater reduction in social anxiety severity had a correction in this pattern of neural activation. Specifically, greater improvement in social anxiety severity from pre- to post-treatment was associated with more positive functional connectivity between the amygdala and fusiform face area in self-referential processing versus other-referential processing compared to individuals who experienced less change in social anxiety severity. This suggests that improvements in social anxiety symptoms may be associated with a correction of dysfunctional connectivity, from negative connectivity at baseline to positive connectivity at post-treatment, between the amygdala and fusiform face area during self-referential processing. One possibility is that at baseline, visual processing is more independent of amygdala activation, such that rather than reacting to the visual stimulus, participants with social anxiety detect threat and react strongly. Perhaps with a reduction in social anxiety severity, participants demonstrate greater stimulus-driven reactivity, reflected in stronger connectivity between affective circuitry (amygdala) and visual processing regions (FFA).

At pre-treatment, the social anxiety group had more positive functional connectivity between the amygdala and the insula during self-referential processing versus other-referential processing compared to healthy controls. The insula is involved in the detection of negative stimuli and monitoring of bodily sensations, which are both common in conditions predisposed to anxiety, and acts as a trigger for anxious responding, which is associated with heightened amygdala activation (Paulus and Stein, 2006). In the group that received treatment, the difference in insula activation during self- vs other-referential processing decreased from pre- to post-treatment. The opposite finding emerged for the waitlist group. This finding suggests the possibility that treatment may have led to reduced interoceptive sensitivity, which was reflected in less activation of the insula during observation of an aversive stimulus. Alternatively, the self-referential stimulus may have been less distressing for those who received treatment, and perhaps more distressing for those on the waitlist.

In this scenario, self-referential processing may have elicited a stronger bodily reaction in the waitlist group, which was reflected in greater insula activation during self versus other.

There were no major differences in neural activation during self-referential processing between the group randomized to CBT versus ACT. The only difference that emerged was in activation of the putamen, which was greater for self-referential processing relative to other-referential processing at post-treatment for those in ACT relative to CBT. Reactivation of the putamen is associated with anxiety-related distress (Carlisi et al., 2017), though other studies have reported opposite effects (Etkin and Wager, 2007). For these reasons, it is difficult to interpret this finding, especially in light of the comparable treatment response between CBT and ACT in self-report and clinician-rated anxiety in the parent trial (Craske et al., 2014). However, the putamen should be explored as an area for future investigation in the context of self-referential processing in social anxiety disorder.

Contrary to expectations, pre-treatment alterations in prefrontal cortex (PFC) and amygdala activation were not observed. This was somewhat surprising given that the amygdala and PFC regions are implicated in threat encoding, threat detection and fear expression across species and tasks (LeDoux, 2014). One possibility is that the task may have evoked a negative self-comparison response rather than a fear response. Unfortunately, we did not assess self-report ratings of negative social comparisons in response to the task. However, at post-treatment
across all participants (treatment and waitlist), there was enhanced positive connectivity between the right amygdala and the ventromedial prefrontal cortex during self-relative to other-referential processing. A robust body of literature suggests that positive connectivity between the amygdala and prefrontal cortex is important for emotion regulation (Brühl et al., 2014; Etkin and Wager, 2007). However, when the analyses were reduced to include only the treatment condition, this effect was only marginally significant, potentially due to a smaller sample size. Therefore, this finding should be interpreted with caution.

Several key limitations of the current study are noteworthy. The first is the small sample size for the healthy control group, due to the focus in the larger study on social anxiety disorder. Second, there were only two opportunities for self-observation as well as for other-observation, precluding an opportunity to determine habituation or other time-course effects over multiple stimulus presentations. Third, the other-observation including the presentation of a well-known national news anchor, which might have resulted in differential patterns of activation compared to the observation of a novel stimulus. However, given that self-referential processing was the key construct under scrutiny in this study, familiarity with the other stimuli does not appear to be a critical confounding variable. In fact, a familiar news anchor was included to control for effects of differential familiarity as novel faces may elicit greater amygdala activity. Finally, as participants did not provide any behavioral responses during the task, we are unable to confirm that participants were focused on the task.

In conclusion, this is the first study to demonstrate differential neural activation during self-referential processing in social anxiety disorder compared to healthy controls using a video observation of a speech performance, a task common in the treatment of social anxiety disorder. Key areas of differences during self-referential processing included visual processing regions including the fusiform face area and extrastriate body area, and insula. The amygdala demonstrated differences in functional connectivity to these and other regions based on social anxiety severity, with more positive functional connectivity between the amygdala and insula during self-referential processing for those with social anxiety disorder. In individuals who received treatment for social anxiety, improvements in sensory processing regions were observed. Finally, greater improvement in social anxiety from pre- to post-treatment was associated with more positive functional connectivity between the amygdala and fusiform face area during self-referential processing at post-treatment. These findings suggest that self-referential processing is disrupted in social anxiety disorder, which may play a key role in maintaining anxiety and related impairments, and that corrections in social anxiety severity are reflected in neural changes from pre- to post-treatment in the activation and connectivity with sensory processing regions during self-referential processing.

Contributors

Dr. Brown conceptualized the study, analyzed the data in collaboration with Drs. Young and Torre, interpreted the results, and wrote up the manuscript. Dr. Goldin, Davies, and Niles assisted with the interpretation of the results. Drs. Burkland and Saxbe assisted with data collection and interpretation. Dr. Craske and Lieberman designed the study and oversaw data collection.

Conflicts of Interest

Drs. Craske, Brown, Lieberman, Young and Goldin received funding from the National Institute of Health. Dr. Brown reported receiving funding from the Department of Defense.

Funding Information

This project was funded by the National Institutes of Mental Health R21 MH081299 (PIs: Craske, Lieberman and Taylor). The sponsor was not involved in the interpretation or reporting of study results.
