IN PRESS AT HEALTH PSYCHOLOGY
Abstract

**Objective:** The current study tested whether neural activity in response to messages designed to help smokers quit could predict smoking reduction, above and beyond self-report. **Design:** Using neural activity in an *a priori* region of interest (a subregion of medial prefrontal cortex; MPFC), in response to ads designed to help smokers quit smoking, we prospectively predicted reductions in smoking in a community sample of smokers (n=28) who were attempting to quit smoking. Smoking was assessed via expired carbon monoxide (a biological measure of recent smoking) at baseline and one month following exposure to professionally developed quitting ads. **Results:** A positive relationship was observed between activity in our MPFC ROI and successful quitting (increased activity in MPFC was associated with a greater decrease in expired CO). The addition of neural activity to a model predicting changes in CO from self-reported intentions, self-efficacy and ability to relate to the messages significantly improved model fit, doubling the variance explained ($R^2_{self-report}=.15$, $R^2_{self-report+neural activity}=.35$, $R^2_{change}=.20$). **Conclusion:** Neural activity is a useful complement to existing self-report measures. In this investigation, we extend prior work predicting behavior change based on neural activity in response to persuasive media to an important health domain and discuss potential psychological interpretations of the brain-behavior link. Our results support a novel use of neuroimaging technology for understanding the psychology of behavior change and facilitating health promotion.
Neural Activity Predicts Reductions in Smoking Above and Beyond Self-Report

We are exposed to messages designed to change our health behaviors nearly every day; parents and friends may encourage us, doctors may instruct us, and public health media campaigns try to persuade us to make healthier lifestyle choices. In attempting to understand the circumstances under which these types of messages are likely to result in behavior change, prominent persuasion and behavior-change theories have demonstrated that people’s self-reported intentions and self-efficacy predict message-consistent behavior change (Ajzen, 1991; Chaiken, Liberman, & Eagly, 1989; Fishbein & Ajzen, 1975; Fishbein et al., 2001; Petty & Cacioppo, 1986; Rosenstock, 1966; Strecher & Rosenstock, 1997). However, models based on self-report measures have limitations. For example, one recent meta-analysis reported that the Theory of Planned Behavior accounted for 27% of the variability in people’s behavior, leaving nearly three quarters of the variability unexplained (Armitage & Conner, 2001), and a separate meta-analysis reported a slightly weaker average intention-behavior link (Webb & Sheeran, 2006). Presumably, predictive efficacy is partially limited by moderating events and changing circumstances that occur after predictions can be made and thus cannot be accounted for in such models. Nevertheless, it is also likely that a share of unexplained variance could be captured with new measurement instruments that do not share some of the biases associated with self-report methods.

Neuroimaging as a tool to predict behavior change

Some of the difficulty in predicting behavior change following persuasive messages, and consequently identifying messages that are likely to have the greatest impact in affecting health behavior change, may stem from limitations in peoples’ ability to produce accurate self-reports in the context of laboratory or focus group settings, or in retrospective surveys. For example,
limitations and biases may arise due to social desirability effects (Booth-Kewley, Larson, & Miyoshi, 2007; Edwards, 1953), and/or when people do not have conscious access to the factors that lead them to change their behaviors (Nisbett & Wilson, 1977). Furthermore, when asked, people may confabulate reasons that did not actually factor in to the behavior change (Wilson & Nisbett, 1978). Likewise, introspection during stimulus presentation may change the experience (Wilson & Schooler, 1991).

Among methods for circumventing such challenges (Hurlburt & Heavey, 2001; Nederhof, 2006), functional magnetic resonance imaging (fMRI) provides a way of monitoring neural responses to persuasive messages in the moment that effects initially take hold (Lieberman, 2010). As such, it provides a complementary data source on how people process messages (Chua, Liberzon, Welsh, & Strecher, 2009; Chua, Polk, Welsh, Liberzon, & Strecher, 2009) that may allow us to more accurately predict behavior change following message exposure (Falk, Berkman, Harrison, Mann, & Lieberman, 2010; Lieberman, 2010). Neuroimaging has been used successfully in past investigations to link neural activity during cognitive tasks to changes in substance use behaviors (Brewer, Worhunsky, Carroll, Rounsaville, & Potenza, 2008; Kosten et al., 2006; Paulus, Tapert, & Schuckit, 2005), as well as lower-level attention, memory and reward processes involved in smoking and smoking cessation (Brody et al., 2002; Brody et al., 2007; Mendrek et al., 2006; Weinstein & Cox, 2006; Xu et al., 2007), but has not previously been used to predict changes in smoking reduction in response to persuasive messages. In the context of assessing responses to persuasive messages, understanding the neural precursors of behavior change may ultimately allow us to select among messages those that are most likely to show specific, desired effects and are ultimately more effective in helping people to change their behaviors.
The present approach.

As a starting point, one recent neuroimaging study demonstrated that neural activity during initial exposure to persuasive messages can predict variability in behavior change that is not predicted by self-report measures such as attitudes and intentions (Falk et al., 2010). More specifically, Falk and colleagues reported that activity in a neural region associated with self-related processing (a sub-region of medial prefrontal cortex) was associated with changes in sunscreen use from the week before the scan to the week after, above and beyond people’s attitudes and intentions to use sunscreen.

In the present study, we extend this work to the context of anti-tobacco messages and subsequent smoking reduction. This represents an important step forward theoretically, given that smoking reduction is a more motivationally relevant and complex behavior change than increased sunscreen use. This also represents an important practical step, given that smoking is the leading cause of preventable morbidity and mortality in the United States, and as such is a public health priority ("The 2004 United States Surgeon General's Report: The Health Consequences of Smoking," 2004; CDC, 2008, 2010). Evidence suggests that mass media campaigns can be used to facilitate quitting (NCI, 2008; Popham et al., 1993; Vallone et al., 2010). However, at present the underlying mechanisms that lead messages to be successful are not fully understood.

From a theoretical standpoint, we were also interested in whether neural activity could predict independent variance above and beyond self-report measures. We chose to examine intentions and self-efficacy as self-report variables that have been demonstrated to predict substantial variance in behavior change and are present in several major theories of health behavior change (Fishbein et al., 2001). Interrogating neural activity simultaneously with known
self-report precursors of behavior change (e.g. intention and self-efficacy) will not only allow us to gain a deeper understanding of the brain-behavior link, but may also help us understand the interrelationships between these psychological constructs and behavioral outcomes of interest.

In addition, given that Falk and colleagues (2010) speculated that activity in MPFC might index either and explicit or implicit connection between persuasive messages designed to change behavior and the self, we included a measure of participants’ explicit ability to relate to the messages. This measure may help us to narrow our understanding of whether the variability in behavior change explained by neural activity in our medial prefrontal region of interest is reducible to information obtainable through explicit self-report.

Lastly, self-reports of smoking behavior (either through global recall or through time-line follow-back) are prone to a number of cognitive biases (Hammersley, 1994; Pierce, 2009; Shiffman, 2009). For example, smokers exhibit a tendency to report that they have smoked numbers of cigarettes that cluster around certain round numbers (e.g. 10; 20; the number of cigarettes in a pack), even though this is not reflective of actual behavior (Klesges, Debon, & Ray, 1995). Likewise, bias may arise due to self-presentation concerns, or other factors such as peoples’ motivation to appear consistent with their stated intentions (Cialdini & Goldstein, 2004). Therefore, while having limitations of its own (discussed in the limitations section of this paper), we elected to use a biological indicator of recent smoking (expired carbon monoxide; CO) as our primary dependent variable.

By combining data obtained through fMRI, self-report surveys, and biological indicators of cigarette smoking, we were able to link neural responses during exposure to health messages to the real-world behaviors that follow. More specifically, we demonstrate that activity in an a
priori region of medial prefrontal cortex can be used to explain variability in expired CO in the context of smoking cessation.

Methods

Participants

Thirty-one right-handed participants (15 female) were recruited from the American Lung Association’s Freedom from Smoking program, an eight-week professional-led group-based smoking cessation program, that was standard to all subjects (aside from recruitment, there was no connection between the program and this study). Two male participants were excluded from behavioral follow-up analyses due to missing endpoint data, and one male participant was excluded due to excessive head motion during the fMRI scanner session, resulting in a final sample of 28 participants.

All participants were heavy smokers who intended to quit. Participants were considered heavy smokers if they smoked at least 10 cigarettes per day, 7 days per week, for at least one year, and had urinary cotinine levels of at least 1000 ng/mL. On average participants smoked 21 cigarettes per day (SD=10.0). In addition to enrollment in a cessation program, quitting intentions were assessed via scores >9 out of 10 on the Contemplation Ladder, a single-item measure of intentions to quit (Biener & Abrams, 1991), thus holding baseline intentions to quit relatively constant across this sample. Participants met standard criteria for fMRI scanning; participants were excluded if they were left-handed, did not speak English, were pregnant, claustrophobic, or had any other condition contraindicated for MRI. Participants were also excluded if they consumed more than 10 alcoholic drinks per week, or had any of the following conditions: dependence on substances other than nicotine, dependence on substances within one year of the scan date, neurological or psychiatric disorders, cardiovascular disease. Complete
methodological details and behavior change data available in: (Berkman, Falk, & Lieberman, under review).

Participants varied in age from 28 to 69 ($M=45$, $SD=10.1$), and had been smoking from 11 to 53 years ($M=28.4$, $SD=2.0$). Participants were ethnically diverse: 50% were Caucasian, 25% Hispanic, 21% African American, and 4% other, and socioeconomically diverse: participant mean annual income = $31,070 (range = $0-$200,000); 57% received some form of government assistance; 60% completed some form of college, and 28% received a bachelor’s degree or higher. Participants were paid $80 for completion of the MRI portion of the study. All participants provided written informed consent that was approved by the University of California, Los Angeles Institutional Review Board (IRB).

Materials and Procedure

Upon arrival, participants were given consent and screened for use of following illicit drugs with a urine test (Syva RapidTest d.a.u. 5; Dade Behring Inc., Cupertino, CA, USA): amphetamines, cocaine, marijuana, opiates, and PCP.

Baseline Smoking Measures. Participants completed self-report measures of smoking history, nicotine dependence, cravings, and intentions to quit, as well as exhaled carbon monoxide (CO), a measure of recent smoking (Micro-smokerlyzer; Bedfont Scientific Ltd., Kent, UK). In order to minimize withdrawal effects during the scan, participants smoked a cigarette within one hour of the beginning of the scan.\(^1\) Next, participations received verbal

\(^1\) Attempts were made to standardize the procedural order such that participants smoked as closely as possible to the start of the scan. Some fluctuation in time from the last cigarette to start of the Ads Task did occur given the variability in setting up participants in the scanner, need to repeat instructions and time needed for participants to acclimate to using the button box.
instructions and completed a practice version of the scanner task. Participants also completed a variety of other questionnaires that are not relevant to the present hypotheses.

*The Ads Task.* Professionally developed television commercials designed to help smokers quit smoking were obtained from public health agencies and foundations including the American Legacy Foundation, the California Department of Public Health, the Massachusetts Department of Public Health and the Louisiana Public Health Institute. Discussions with experts at these agencies narrowed the pool of ads to those that would be most relevant to smokers who were trying to quit smoking. Ads focusing on prevention or that did not target current smokers were excluded. A series of sixteen final video-based ads that specifically targeted smokers and encouraged quitting were included. Content included testimonials focusing on danger to the smoker (MA’s “Fight for Your Life” Campaign), humorous ads emphasizing the social value of quitting (LA’s Finger Puppet Campaign), the danger of second hand smoke to others (CA Department of Public Health), encouragement to re-learn behaviors without cigarettes (American Legacy Foundation’s Ex Campaign: “Re-Learn”) and ads empathizing with the difficulty of quitting and suggesting resources to help (American Legacy Foundation’s Ex Campaign: “Direct Response”). All ads were 30 seconds long, with the exception of two ads, which were 15 seconds long.

*fMRI Procedure.* Stimuli were presented using fMRI scanner compatible LCD goggles, and responses were recorded using a scanner compatible button box. Foam padding was used to reduce head motion. During the primary task, each participant watched a series of 16 ads (each of which was designed to help smokers quit smoking) while neural activity was recorded using fMRI. The order of ads was counterbalanced across subjects. Following the presentation of each ad, participants rated the extent to which the ad promoted: a sense of self-efficacy (“This ad
makes me feel that I can quit”); increased intentions to quit (“This ad makes me more determined to quit”); and self-relevance (“I can relate to this ad”). All ratings were made on a 4-point scale (anchors: disagree strongly, disagree somewhat, agree somewhat, agree strongly). Participants were given 4 seconds to make each rating. Ads and ratings were interspersed with rest periods in which participants viewed a fixation-cross and were instructed to clear their minds. Additional 15-second fixation-cross rest periods were interspersed every 4 blocks in order to allow the hemodynamic response to return to baseline.

*fMRI data acquisition.* Brain imaging data were acquired on a 3T Siemens Trio scanner at the UCLA Ahmanson-Lovelace Brain Mapping Center. High-resolution structural T2-weighted echo-planar images (spin-echo; TR = 5000 ms; TE = 34 ms; matrix size 128 x 128; 34 axial slices; FOV = 192mm; 4 mm thick) were acquired coplanar with the functional scans. One functional scan lasting 11.5 minutes (351 volumes) was acquired during the task (echo-planar T2*-weighted gradient-echo, TR = 2000 ms, TE = 30 ms, flip angle = 90°, matrix size 64 x 64, 34 axial slices, FOV = 192 mm; 4 mm thick).

*Follow up smoking measures.* Approximately one month following the baseline portion of the study, an in-person follow-up was conducted in the field, including a biological verification of participants’ self-reported smoking (through expired CO). At this stage, two participants were unable to be reached.

*Data Analysis*

*fMRI Data Analysis.* The imaging data were preprocessed using a combination of FSL tools (FMRIB Software Library; Oxford University, Oxford, UK) and SPM8 (Wellcome Department of Cognitive Neurology, Institute for Neurology, London, UK). All images were brain-extracted using BET (FSL’s Brain Extraction Tool) and realigned within runs using
MCFLIRT (FSL’s Motion Correction using FMRIB’s Linear Image Registration Tool), then checked for residual motion and noise spikes using a custom automated diagnostic tool (thresholded at 2mm motion or 2% global signal change from one image to the next). At this stage, one participant was excluded due to extreme head motion. In SPM8, all functional and anatomical images were reoriented to set the origin to the anterior commissure and the horizontal ($y$) axis parallel to the AC-PC line. Also in SPM8, functional images were corrected for slice acquisition timing differences within volumes, realigned within and between runs to correct for residual head motion, and coregistered to the matched-bandwidth structural scan using a 6-parameter rigid body transformation. The coregistered structural scan was then normalized into the Montreal Neurological Institute (MNI) standard stereotactic space and these parameters were applied to all functional images. Finally, the normalized functional images were smoothed using an 8 mm full width at half maximum Gaussian kernel. All functional imaging results are reported in MNI coordinates.

The task was modeled separately for each subject, using a blocked design in SPM5 (Wellcome Department of Cognitive Neurology, Institute for Neurology, London, UK). Initial analyses modeled ad exposure compared to a fixation rest period. Response periods were modeled as effects of no interest in the present analysis given that our primary interest lay in understanding real-time neural responses to the ads. A corresponding random effects model averaged across results at the single subject level.

*A priori regions of interest.* The primary region of interest was constructed using Marsbar (Brett, Anton, Valabregue, & Poline, 2002), based on prior work predicting behavior change from neural activity (Falk et al., 2010). The region of interest encompassed a ventral subregion of medial prefrontal cortex that was most highly associated with behavior change in work by
Falk and colleagues (2010; Figure 1). Thus, we refined the prior approach to capitalize on the whole-brain exploratory search conducted in that prior investigation. Average parameter estimates of activity in this ROI were extracted at the group level using Marsbar.

*Associations between neural activity during ad exposure and changes in CO.* We used changes in expired CO from baseline to endpoint as our primary proxy for behavior change; change was calculated as the difference between endpoint expired CO and baseline expired CO (positive values indicate more successful quitting). In order to determine whether activity during ad exposure in our *a priori* region of interest was associated with behavior change, behavior change scores were regressed onto parameter estimates of activity from the region of interest. In order to determine whether neural activity explained variability in behavior change that was not explained by self-report measures of intention, self-efficacy and ability to relate to each ad, these measures were also entered into a regression model, predicting behavior change from neural activity, controlling for all self-report measures collected in the scanner.

Complementary whole brain searches were conducted with a voxel-wise threshold of $p<.005$ combined with a minimum cluster size of 18 in medial prefrontal cortex (given our *a priori* hypothesis) and 42 in the rest of the brain, corresponding to $p<.05$, FDR corrected for each search space, based on a Monte Carlo Simulation implemented using AlphaSim in the software package AFNI ([http://afni.nimh.gov/afni/doc/manual/AlphaSim](http://afni.nimh.gov/afni/doc/manual/AlphaSim)).

More specifically, in these whole-brain searches, we regressed neural activity onto changes in CO, as well as changes in CO, controlling for self-report measures. A design matrix was constructed for each subject at the single subject level comparing activity while viewing the ads to activity at rest. At the group level, activity during the ads (compared to rest), was then correlated with subsequent changes in expired CO (table S1). A parallel regression was run at
the group level assessing the relationship between activity during ad exposure and changes in CO, controlling for intentions, self-efficacy, and average ability to relate to the ads.

Results

*Smoking behavior change.* At baseline, participants were all heavy smokers (see recruitment criteria), and smoked an average of 21.12 (SD=10.04) cigarettes per day, corresponding to a baseline expired CO average of 19.21ppm (SD=11.37). At one month follow-up, participants smoked an average of 5.00 (SD=5.42) cigarettes per day, corresponding to an endpoint expired CO average of 12.07ppm (SD=10.72). This represented a significant decline: average change in expired CO = 7.14ppm (SD=14.15), t(27)=2.672, p=.013; average change in cigarettes 16.13 cigarettes per day (SD=11.30), t(27)= 7.55, p <.01 (Berkman et al., under review). The correlation between self-report smoking behavior* and our biological measure of expired CO was significant both at baseline (r = .44, p=.02) and endpoint (r=.48, p=.009).

*Behavioral responses to the ads task.* One-sample t-tests comparing to neutral on a 4-point scale from strongly disagree to strongly agree suggested that on average, participants could relate to the ads: M=2.85, SD=.44, t(27) = 4.225, p<.001; that exposure to ads significantly reinforced participants’ intentions to quit smoking: M=2.80, SD=.56, t(27) = 2.757, p=.010; and significantly increased their self-efficacy to quit: M=2.75, SD=.49, t(27) = 2.712, p=.012.

*Associations between self-reported intentions, self-efficacy and expired CO.* The averaged values for intention and self-efficacy measures were highly correlated with one another between subjects (r=.93, p<.001), and were each significantly correlated with the degree to

---

2 As reported elsewhere (Berkman et al., under review), due to non-normality of the self-report (number of cigarettes) variables, baseline and endpoint number of cigarettes were log-transformed prior to conducting statistical tests.
which participants could relate to the ads as a whole ($r_{\text{intention\_relate}} = .442, p=.018,$ $r_{\text{self\_efficacy\_relate}} = .53, p=.004$). Likewise, within subjects, each of the self-report measures were significantly correlated, $p<.05$ (the average within subjects correlation between individual ratings of intention and self-efficacy was .62; between intention and ability to relate was .55; and between self-efficacy and ability to relate was .58). Due to the extremely high degree of multicolinearity between intention and self-efficacy between subjects, a composite intention/self-efficacy measure was calculated as the average of the two measures, within subjects, for the purpose of multiple regression analyses predicting behavior change (thus “self-report” measures referred to below include a composite intention/self-efficacy variable, and the relate variable). Table 2 includes correlations between each of the self-report measures and neural activity, between subjects.

*Neural activity during ad exposure predicts subsequent changes in expired CO.* In order to determine whether neural activity in our *a priori* hypothesized region of medial prefrontal cortex was associated with behavior change, changes in expired carbon monoxide (CO) from baseline to one month post-scan were regressed onto parameter estimates of activity during ad exposure compared to rest. Neural activity in this region of interest during ad exposure significantly predicted behavior change, both before ($\beta=.42, t(26)=2.35, p=.027$) and after ($\beta=.45, t(24)=2.75, p=.011$) controlling for self-reported intentions to quit, self-efficacy to quit and ability to relate to each ad (Figure 2b), such that increased activity in MPFC was associated with greater declines in expired CO. Complementary whole-brain analyses also identified a small number of other regions as associated with behavior change outside of our hypothesized region of medial prefrontal cortex. Three clusters of neural activity in the second most common region implicated in self-related processing (medial precuneus/posterior cingulate; peak cluster 1: $t(26)=3.67; peak$
cluster 2: t(26)=4.77; peak cluster 3: t(26)=3.97; all ps<.005) and a region involved in motor planning (supplementary motor area; t(26)=3.75, p<.005) were the regions most highly associated with behavior change. Complete tables of results, before and after controlling for self-report variables, are available in the supplementary online materials.

In order to determine the amount of variability in behavior change that could be explained above and beyond self-report, we tested a series of linear regression models, successively adding variables to the model. $R^2$ values were compared for models with self-report variables alone ($R=.382$, $R^2=.146$) and with neural activity in our functionally defined ROI plus all self-report measures ($R=.592$, $R^2=.351$). This comparison revealed that an additional 20% of the variability in participants’ behavior change could be explained using neural activity, above and beyond variables accounted for in traditional models of behavior change ($R^2$ change = .20, $F(1,24)=7.55$, $p=.011$). Put another way, the addition of neural activity to the model more than doubles the amount of variance explained, and represents a significant improvement in the model (Table 1; Figure 2b). Conversely, when neural activity from our functional region of interest is first entered into the model, followed by self-report predictors (intention, self-efficacy, and ability to relate to the messages), a marginally significant improvement is observed ($R^2$ change including intention, self-efficacy and relate variables in addition to medial prefrontal cortex = .175, $F(1,24)=3.24$, $p=.057$).

Thus, neural activity and self-report predict independent variance in changes in expired CO; neural activity during exposure to ads designed to help smokers quit smoking more than doubles the variability explained in subsequent behavior change (as inferred by CO scores), as compared to self-report measures alone and significantly improves model fit. The combination of all self-report measures collected plus neural activity results in the greatest proportion of
variability explained, with the brain and self-report contributing equal portions of independent variance in this case.

Discussion

In this investigation, we extend prior results demonstrating the ability of neural responses to persuasive messages to predict real-world outcomes to the context of smoking reduction. We targeted smokers who were already taking action to quit, holding stage of change constant across our sample. We also extended prior results by demonstrating that the variability in behavior change predicted by neuroimaging data is independent of self-efficacy and ability to relate to the messages viewed, in addition to being independent of measures captured in prior studies such as intentions to change.

We report that activity in an identical sub-region of medial prefrontal cortex that was associated with behavior change in a prior, independent study of sunscreen behavior change (Falk et al., 2010), was associated with changes in expired CO following exposure to professionally developed quitting ads. This relationship (increased MPFC → greater decrease in expired CO) remained significant after controlling for self-reported intentions and self-efficacy, two common measures used to predict behavior change, as well as participants’ self-reported ability to relate to the ads. Consistent with prior findings (e.g. (Falk et al., 2010) found that neural measures explained an additional 23%), neural activity in our region of interest explained an additional 20% of the variability in expired CO, above and beyond self-reported intentions, self-efficacy and ability to relate to the ads, doubling the variability explained in comparison to traditional self-report alone.

In considering the psychological mechanisms that might link the observed neural activity to behavior change, we hypothesize a self-processing mechanism; activity in medial prefrontal
cortex is implicated in nearly all studies of self-related processing (Lieberman, 2010). The idea that self-processing may link neural activity to behavior change is also consistent with research suggesting that people who become more absorbed in the narrative of anti-smoking commercials report increased benefit (Dunlop, Wakefield, & Kashima, 2008), that messages that are self-relevant are more effective than messages that target generic individuals (Dietz, Delva, Woolley, & Russello, 2008; Strecher et al., 2008; Strecher, Shiffman, & West, 2005), that messages that are tailored activate medial prefrontal cortex more than messages that are not personally tailored (Chua, Liberzon, et al., 2009) and with theories that highlight self-related processes as predictors of behavior change (Ajzen & Fishbein, 1980; Fishbein et al., 2001; Strecher & Rosenstock, 1997).

Given that several prominent theories of behavior change (Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975; Fishbein et al., 2001; Strecher & Rosenstock, 1997) touch on self-related processing of different varieties, prior work (Falk et al., 2010) speculated that activity in our MPFC region of interest might reflect activation of either implicit or explicit connections between message content and the self. In the current investigation, we tested one measure of explicit connection between the self and the message (ability to relate to the message). We found that self-reported ability to relate to messages predicted variability independent of neural activity in medial prefrontal cortex. This explicit measure may be useful in understanding the process of behavior change, however, it does not explain the medial prefrontal cortex-behavior relationship. Our findings do not rule out a different form of self-related processing, and informal debriefing with subjects several weeks post-scan suggested that many of the ads that did not seem immediately relevant at the time of the scan emerged as especially relevant and helpful as they engaged in the process of quitting. One interpretation that is consistent with these
participant observations is that medial prefrontal cortex activity in this context reflects an implicit connection between the self and the behavior in question (in this case quitting); the particular ventral subregion of medial prefrontal cortex targeted in our investigation has also been implicated in implicit valuation and affective judgments, independent of conscious awareness (Moran, Heatherton, & Kelley, 2009; Rameson, Satpute, & Lieberman, 2010).

It is also possible that neural activity in medial prefrontal cortex may capture a different type of process that is distinct from intention, self-efficacy and ability to relate to message content, that can be pinpointed in future investigations. Regions of medial prefrontal cortex in the vicinity of the region observed by Falk and colleagues to predict behavior change have been associated with framing effects (Chua, Liberzon, et al., 2009; Chua, Polk, et al., 2009), implicit preferences (Mcclure et al., 2004), considering personally relevant future goals (D'Argembeau et al., 2010), and valuing stimuli in terms of expected outcomes with respect to the current situation (Cunningham, Zelazo, Packer, & Van Bavel, 2007).

Building on evidence that medial prefrontal cortex activity is associated with envisioning personal goals when envisioning future events (D'Argembeau et al., 2010), as well as weighing costs and benefits of stimuli against current experience (Cunningham et al., 2007), it is possible that increased MPFC activity in our ROI supports envisioning oneself carrying out the behavior in question. This interpretation is consistent with classic work suggesting the importance of providing a specific action plan in affecting behavior change (Dabbs & Leventhal, 1966; Leventhal, Singer, & Jones, 1965; Leventhal, Watts, & Pagano, 1967). This interpretation is also consistent with the observed relationship between activity in other self-related processing regions (e.g. medial precuneus/posterior-cingulate) as well as a region involved in motor planning (supplementary motor area) in whole brain regressions exploring regions associated with
behavior change (Kosten et al., 2006; McClernon, Kozink, Lutz, & Rose, 2009). This coordinated activity might index the extent to which anti-smoking ads prompt participants to engage in planning of specific personal actions needed to carry out the behavior in question.³ Thus, it is possible that while we have focused initially on medial prefrontal cortex as producing a signal that explains a sizeable proportion of variability in behavior change, exploring coordinated activity in medial prefrontal cortex, medial precuneus/posterior-cingulate and supplementary motor area could explain an even greater proportion of variability in subsequent behavior change; more ventral posterior cingulate activity has been observed in other studies in which neural activity during cognitive tasks was associated with subsequent changes in substance use (Brewer et al., 2008; Paulus et al., 2005), and might be explored as an additional region of interest in future studies linking cognitive control to successful quitting. Just as we built upon prior work to refine our understanding of the neural prediction of behavior change, regions identified in whole-brain searches in this investigation can serve to develop even more targeted and sophisticated regions of interest in future work.

Limitations.

Future work may also benefit by addressing limitations of the current study. In particular, given that nicotine alters cerebral blood flow an vascular resistance (Hall, 1972; Miyazaki, 1969; Skinhoj, Olesen, & Paulson, 1973), that the effects in may differ across the brain (Jacobsen et al., 2002), and that acute nicotine administration causes it’s own changes in BOLD signal (Kumari et al., 2003; Stein et al., 1998), the neural activation observed in this study

³ It is interesting to note that activity in these regions is also associated with substance-cue potentiation in abstinent smokers viewing smoking-related cues (McClernon et al., 2009), as well as relapse in cocaine-dependent patients who viewed cocaine-relate-cues (Kosten et al., 2006)). It is possible that both responses to cues prompting quitting and cues prompting activation of substance use activate planning routines that would predict future behavior.
could have been influenced by recency of smoking prior to the scan; future work will benefit by more precisely measuring and controlling time between nicotine administration and task performance. Likewise, it should be noted that the expired CO measure is sensitive to a number of factors other than recent smoking; for example, the measure is sensitive to the recency of smoking (which we attempted to control by allowing all participants to smoke directly before the scan), the brand of CO machine (which was standardized across the study), running and cardiovascular fitness (future investigations might benefit from explicitly recording information pertaining to changes in physical activity habits, however, in the present sample, we are unaware of any major changes in these habits among our participants), proximity to car emissions (which again could be more precisely measured in future investigations, but is unlikely to have shifted dramatically within our smokers over the span of the study), among other factors. Furthermore, expired CO is sensitive to the proximity to others smoking, which we believe is an advantage to this measure in the current investigation because reducing both one’s own smoking, as well as exposure to others who are smoking are important to long-term health. Expired CO presents the advantage of being a biological index of recent smoking, and parallels other investigations using fMRI to examine outcomes in cocaine dependent patients (Brewer et al., 2008) and to test compliance in other fMRI/ smoking investigations (McClernon et al., 2009), however, as in the present study, future investigations will also benefit from observing the similarities and differences between such biological measures and more traditional self-report measures. To the extent that these issues were present in the current data set, each would have impaired our ability to predict outcomes from brain data. However, controlling such factors in the future may allow investigators to predict outcomes more precisely.

Conclusion
The results of this investigation provide convergent evidence that neural activity can predict behavior change, above and beyond self-report. Given that self-report and neural activity explain independent portions of the variability in behavior change, neuroimaging methods can be viewed as a complement to existing self-report methods, indexing processes that may be inaccessible to conscious awareness or otherwise uncaptured through self-report. The specific psychological mechanisms linking neural activity to behavior change will be of interest to future investigations, where tests of affective vs. cognitive and implicit vs. explicit self-processes, as well as the role of envisioning the future self in the context of goals may yield especially fruitful results. Networks of activity including regions from both the self-related processing network and areas implicated in motor planning may also serve as particularly useful targets for future research. Finally, pinpointing psychological mechanisms that link neural activity to behavior change will both help us connect our understanding of the brain to classic work in health psychology. This will also be of use in updating our understanding of behavior change, and generating novel self-report measures that could be used in a wider context to explain variability that is currently accounted for using fMRI. The current results bring us one step closer to the ability to use fMRI to select messages that are most likely to affect behavior change both at the individual and population levels, and further suggest that brain may provide information that introspection does not.
Table 1. Results of hierarchical regression predicting changes in smoking as indicated by expired carbon monoxide (CO), from self-report measures alone (intention, self-efficacy, ability to relate to ads), and then combining self-report measures with neural activity in an *a priori* defined region of medial prefrontal cortex.

Figure 1. Medial prefrontal cortex region of interest used to predict behavior change. This particular region of medial prefrontal cortex was selected *a priori* based on prior work linking neural activity to behavior change in the context of a simpler health behavior (sunscreen use) over a one week period. In the current investigation, neural activity in this region also predicts smoking reduction in a group of smokers over the course of a month, above and beyond their self-reported intentions to quit, self-efficacy to quit, and ability to relate to ads designed to help people quit smoking.
Figure 2. Variance explained by self-report alone, and self-report combined with neural activity in medial prefrontal cortex. (a) A regression model including self-reported intentions, self-efficacy and ability to relate to messages predicted 14.6% of the variance in behavior change. (b) A regression model including self-report measures plus neural activity during ad exposure in medial prefrontal cortex predicted 35% of the variance in behavior change ($R^2_{\text{change}}=.20^*\)$.  

*p<.05

a. Self-Report Only: $R^2_{\text{Total}} = .146^*$

b. Self-Report and Neural Activity Combined: $R^2_{\text{Total}} = .351^*$
